Interaction between Erythropoiesis and Iron Metabolism in Human β-thalassemia - Recent Advances and New Therapeutic Approaches

Nadia Maria Sposi

Abstract

For its frequency and severity β-thalassemia represents a significant health problem in various areas of the world. Progressive iron overload is a common complication of hemoglobinopathies and represents a major cause of morbidity and premature mortality in patients with β-thalassemia. The discovery of hepcidin and its role in iron homeostasis has revolutionized our understanding of the pathogenesis of iron overload and iron-restricted anemias, stimulating the development of new diagnostic and therapeutic modalities for these disorders. However, little is known about the relationship among ineffective erythropoiesis, the role of iron-regulatory genes, and tissue iron distribution in β-thalassemia. The chapter describes evidences for these relationships and discusses how recent discoveries on iron metabolism and erythropoiesis could lead to new therapeutic approaches and better clinical care of these diseases.

Keywords: Thalassemia, Erythropoiesis, Iron Metabolism, Hepcidin, Ferroportin

1. Introduction

In recent years there has been important advancement in our knowledge of iron metabolism regulation that also has implications for understanding the pathophysiology of some human disorders such as beta-thalassemia (β-thalassemia) and other overload diseases. Progressive iron overload has become a major cause of morbidity and premature mortality in patients with β-thalassemia. However, little is known about the relationship among ineffective erythropoi-

esis, the role of iron-regulatory genes, and tissue iron distribution in β-thalassemia. Our understanding of the pathogenesis of iron-restricted anemias and iron overload has been revolutionized by the discovery of hepcidin and its role in iron homeostasis, stimulating the development of new diagnostic and therapeutic modalities for these disorders. Further work is required to understand the mechanisms of hepcidin regulation by iron and erythroid activity and to understand the structure, the transport function and the complex regulation of the hepcidin receptor ferroportin. The chapter describes evidences for these relationships and discusses how recent discoveries on iron metabolism and erythropoiesis could lead to new therapeutic approaches and better clinical care of these diseases, thereby yelding a much better quality of life for patients suffering from iron disorders and anemias.

2. Overall view on β-thalassemia

β-thalassemias are a group of hereditary blood disorders characterized by the reduced (β$^+$ or β^{++}) or absent (β^0) synthesis of the β-globin chains of the hemoglobin (Hb) tetramer. The term thalassemia is derived from the Greek words *thalassa* (sea) and *haima* (blood) and is one of the most common autosomal recessive disorders worldwide. β-thalassemia is prevalent in Mediterranean countries, the Middle East, Central Asia, Far East, as well as countries along the Americas (Fig.1). The highest incidences are reported in Cyprus (14%), Sardinia (12%) and South-East Asia [1–3]. The high gene frequency of β-thalassemia in these regions is most likely related to the selective pressure from Plasmodium falciparum malaria [1–2]. Carriers of β-thalassemia are indeed relatively protected against the invasion of Plasmodium falciparum. However, because of population migration and intermarriage between different ethnic groups, β-thalassemia is, at present, also common in Northern Europe, North and South America, the Caribbean and Australia [4]. The inability to synthesize β-globin chains results in an excess of α-globin chains that precipitate in red cell precursors and cause abnormal cell maturation and their premature destruction in the bone marrow (ineffective erythropoiesis). Red cells that survive to reach the peripheral circulation are prematurely destroyed in the spleen. The clinical manifestations of β-thalassemia are extremely diverse, spanning a broad spectrum from the transfusion-dependent state of thalassemia major (TM) to the asymptomatic state of hetero-zygous carriers for β° or β$^+$ (thalassemia trait).

β-thalassemias can be classified into:

- Thalassemia major

- Thalassemia intermedia

- Thalassemia minor

β-thalassemia with associated Hb anomalies:

- Hb C/β-thalassemia

- Hb E/β-thalassemia

- Hb S/β-thalassemia

Figure 1. Thalassemia distribution and most common β-thalassemia mutations in different countries.

Hereditary persistence of fetal Hb and β-thalassemias

Autosomal dominant forms

β-thalassemia associated with other manifestations:

• β-thalassemia- tricothiodystrophy

• x-linked thrombocytopenia with thalassemia

Many different mutations cause β-thalassemia. They are inherited in a multitude of genetic combinations responsible for a heterogeneous group of clinical syndromes. Thalassemia minor, also known as β-thalassemia trait or heterozygous β-thalassemia, is caused by the presence of a single β-thalassemic mutation and a normal β-globin gene on the other chromosome. Microcytosis, hypochromia, increased HbA2 level and mild or minimal anemia are the characteristic hematological features of beta-thalassemia carriers. The β-thalassemia carrier state is clinically asymptomatic and needs no specific treatment. Thalassemia major, also known as Cooley's anemia or homozygous β-thalassemia, is a clinically severe disorder that results from the inheritance of two β-thalassemia alleles, one on each copy of chromosome 11. Patients have a severe microcytic and hypochromic anemia, associated with increased number of red blood cells and low mean corpuscular volume (MCV) and mean corpuscular Hb (MCH). Peripheral blood smear shows, in addition to microcytosis and hypochromia, anisocytosis, poikilocytosis and nucleated red blood cells (e.g., erythroblasts) [4]. The anemia of thalassemia major is so severe that chronic blood transfusions are usually required. Repeated transfusions and increased iron absorption lead to iron deposition in many organs (liver, endocrine tissues, heart) and ultimately death unless chelation therapy is used [5]. Hemoglobin analysis shows mainly HbF plus a small amount of HbA_2 in β^0 homozygotes, but insufficient to compensate

for the loss of HbA, and the Hb level remains <5 g/dL [5]. Most β^+ homozygotes and $\beta^+\beta^0$ compound heterozygotes also have thalassemia major. HbF remains the predominant hemoglobin but with variable amounts of HbA depending on the specific β^+ thalassemia allele [5]. The term β-thalassemia intermedia (TI) is applied to a less severe clinical phenotype in which significant anemia occurs but chronic transfusion therapy is not absolutely required. Patients show a markedly heterogeneous hematological picture, ranging in severity from that of the β-thalassemia carrier state to that of thalassemia major [4]. Most patients affected by thalassemia intermedia are homozygotes or compound heterozygotes for β-thalassemia, meaning that both β-globin loci are affected. Less commonly, only a single β-globin locus is affected, the other being completely normal. The mild clinical characteristics of TI compared with thalassemia major result primarily from the inheritance of two β-thalassemia mutations, one mild and one severe; the inheritance of two mild mutations or, occasionally, the inheritance of complex combinations, such as two β-thalassemia mutations co-inherited with heterozygous α-thalassemia. In this last form, known as $\alpha\beta$-thalassemia, the α-thalassemia allele reduces the burden of unpaired α-globin chains [6–9]. Table 1 shows some of the commonest causes of thalassemia intermedia. The β-globin gene maps in the short arm of chromosome 11 an 80 Kb region also containing the δ globin gene, the embryonic ϵ gene, the fetal Aγ and Gγ gene [4]. The five functional globin genes are arranged in the order of their developmental expression (Fig 2) [4]. The β-globin gene is regulated by an adjacent 5′ promoter in which a Tata, CAAT and duplicated CACC boxes are located [4]. A major regulatory region, containing also a strong enhancer, maps 50 Kb from the β-globin gene. This locus control region (LCR) contains four (HS-1 to HS-4) erythroid specific DNAse hypersensitive sites (HS$_\text{s}$) containing a variety of binding sites for erythroid transcription factors [4,10–11]. The LCR together with the proximal cis-element transcription factors controls the developmental stage specific expression of genes: from ϵ to γ, and from γ to β and δ during development from embryo to adult. Very early in gestation there is a switch from ϵ to γ-globin production. The fetal hemoglobin (HbF) reaches a plateau after 10– weeks and remains high until 2– years after birth, when it begins to decrease to 0.5–1 % of total hemoglobin in adult red blood cells. The β-globin chain synthesis starts at 30–35– weeks of gestation contributing at this time to 10% of the total hemoglobin. After birth it increases to 97 % forming the adult hemoglobin HbA. The other type of adult hemoglobin is the HbA$_2$ formed by δ chains whose synthesis begins at the 7 th– month of gestation reaching 2–3% in adult life (Fig 2) [12]. Forms of β-thalassemia arise from mutations that affect every step in the pathway of globin gene expression: transcription, processing of the mRNA precursor, translation of mature mRNA, and post-translational integrity of the β-polipeptide chain [13]. Over 200 different thalassemia alleles of the β-globin gene have been reported; the vast majority are caused by point mutations within the gene or its immediate flanking sequences. The distribution of alleles is highly variable from one population to another but within each population there are only a few alleles that are common (Fig 1) [5]. While most alleles behave as Mendelian recessives, there are variants that cause a disease phenotype even when present in a single copy. These act in a dominant negative fashion and are referred to as dominantly inherited β-thalassemias [5]. Conditions with HbF production high enough to give good compensation are known as hereditary persistence of foetal hemoglobin (HPFH) and homozygotes are clinically unaffected while compound heterozygotes with β-thalassemia are very mild [5]. Fetal hemoglobin is a much more common and major modifier of disease severity in individuals with β-thalassemia. In normal individ-

uals only 5-8% of red cells, called F cells, contains HbF,amounting to 5-20% of the total hemoglobin in those cells [14,15]. In the context of a severe deficiency of β-globin synthesis, even the low levels of γ-globin in F cells reduce the relative excess of a α -globin and provide a potent selective survival advantage for cells making HbF in the context of the ineffective erythropoiesis characteristic of the most severe forms of β-thalassemia [14]. Some β-thalassemia mutations increase " per se" the γ-globin gene synthesis, i.e. deletion and non deletion $\delta\beta$-thalassemia or deletions of the 5' region of the beta-globin gene. Also mutations associated with deletion and non-deletion HPFH linked to the β-globin gene cluster are characterized by increasing HbF production. Recently, the genome-wide association studies (GWAS) revealed genetic elements not linked to the β-globin gene cluster, able to modify the severity of the homozygous β^0- thalassemia. In particular, two new regulatory pathways leading to increased γ-globin expression have been identified, i.e. BCL11A and HBS1L-MYB. Both seem to act directly or indirectly affecting the production of repressor proteins that specifically target the γ-globin genes [16]. The clinical phenotype of homozygous β-thalassemia may also be modified by co-inheritance of other genetic variants mapping outside the globin clusters:. the presence of $(TA)_7$ polymorphism in the promoter region of the uridine diphosphate-glucuro-nosyltransferase gene is a risk factor for the development of cholelitiasis in thalassemia major and intermedia patients; the apolipoprotein E $\varepsilon4$ allele and some HLA haplotypes, which seem to be genetic risk factors for left ventricular failure in homozygous beta-thalassemia; a polymorphism in glutathione-S transferase M1 gene has been associated with an increased risk of heart iron overload in thalassemia major [1]. The expression of β-globin genes is also affected by point mutations belonging to three different categories: mutations of promoter and 5'UTR lead to defective β-gene transcription; mutations of splice-junction and 3'UTR affect mRNA processing; and non-sense, frameshift, and initiation codon mutations result in abnormal mRNA translation. Phatophysiology of β-thalassemia can be summarized as follows: the reduced amount or absence of β-globin chains result in a relative excess of unbound α-globin chains that precipitate in erythroid precursors in the bone marrow. Aggregation, denaturation and degradation of these chains lead to the formation of insoluble precipitates as well as hemichromes, which damage cell membranes leading to their premature death and hence to ineffective erythropoiesis. Red cells hemolysis within the circulation and membrane binding of IgG and C3 causes loss of red cells in the spleen. The resulting anemia leads to diminished tissue oxygenation, an increase in erythropoietin levels and bone marrow stimulation and expansion causing skeletal deformities and osteopenia. Substances released from damaged red cells increase iron absorption contributing to iron overload [14]. Diagnosis of β-thalassemia is based on hematologic and molecular genetic testing. Differential diagnosis is usually straightforward but may include genetic sideroblastic anemias, congenital dyserythropoietic anemias and other conditions with high levels of HbF. Genetic counseling is recommended and prenatal diagnosis may be offered. Prognosis of thalassemia minor subjects is excellent. Individuals with thalassemia intermedia may require splenectomy, folic acid supplementation, treatment of extramedullary erythropoietic masses and leg ulcers, prevention and therapy of thromboembolic events. Patients with thalassemia intermedia who do not usually have severe hemosiderosis are less prone to cardiac problems [1,17]. The prognosis of β-thalassemia major was very grim before there was any treatment available. With no treatment, the natural history was for death by age five from infections and cachexia [1]. Treatment of thalassemia major includes regular RBC transfusions, iron chelation and

management of secondary complications of iron overload. In some circumstances, spleen removal may be required. However, many transfusion-dependent patients continued to develop progressive accumulation of iron. This can lead to tissue damage and eventually death, particularly from cardiac disease. The introduction of new iron chelators and chelation regimes associated to the monitoring of myocardial siderosis and cardiac function have converted a once universally fatal disease to a chronic illness. Children treated with chelators since a very young age are expected to have an excellent long-term prognosis [18-19]. Stem cell transplantation is at present the only available definitive cure for patients with thalassemia major but still has a substantial risk of mortality and morbidity. Umbelical cord-blood transplantations have had limited success in the treatment of β-thalassemia because of the large numbers required to sustain hematopoiesis. LV-mediated gene therapy for the β-hemoglobinopathies is now entering early-phase clinical trials and offers great promise. Even if these approaches are successful, such molecular therapies are likely to be expensive and might not be immediately applied to most patients in low-income countries. Much evidence from clinical genetic studies shows that the induction of γ-globin chain synthesis by gene transduction or pharmacological agents would have substantial clinical benefits in patients with β-thalassemia [12,20–26]. However the results obtained have not been sufficiently encouraging to develop large-scale trials [12,24–26]. Furthermore, these agents have several effects, and how any of these drugs work to increase expression of HbF is not fully understood. Recently pre-clinical evidence of potentially new approaches to treating patients with TI and TM has been reported. The evidence for using Tf, hepcidin agonists and JAK2 inhibitors is discussed later in this chapter.

Figure 2. In the top panel, the organization of human β-globin locus is shown. Upstream DNase I hypersensitive sites (HS) within the locus control region (LCR) are displayed. The bottom panel shows the fetal-to-adult hemoglobin switch. This illustration depicts the normal timing of the developmental hemoglobin switches in humans. This figure is adapted from [4] and [12].

Mild deficit in β-chain production	· Homozygosity for silent or mild β-thal
	· Compound heterozygosity for severe and mild β-thal
	· HbE/ β-thal
	· Heterozygous β-thal with ααα or αααα
Reduced α-chain excess	· Homozygous β° or β⁺ thal with 2 or 3 α gene deletions
	· Homozygous β° or β⁺ thal with non deletion α-thal
	· Homozygous β⁺ thal with 1 or 2 α gene deletions
Increased γ-chain synthesis	· Homozygous (δβ)°-thal or (Aγδβ)°-thal
	· Homozygosity for Hb Lepore
	· Compound heterozygosity for Hb Lepore/β-thal
	· Compound heterozygosity for severe β-thal and HPFH
Dominant β-thalassemia	· Highly unstable β-chain variants
	· Bthal heterozygotes with third exon mutations

Table 1. The commonest causes of thalassemia intermedia

3. Overall view on erythropoiesis

The production of red blood cells, known as erythropoiesis, is a developmental system fundamentally under genetic control that involves differentiation of pluripotent hematopoietic stem cells (HSCs) and early multipotent progenitors (MPP) in erythroblasts and mature erythrocytes. Human erythroid differentiation is also regulated and modulated by the interaction of humoral, cellular and molecular processes [27–30]. The erythroid progenitor cell compartment contains the early erythroid progenitors (BFU-E, burst-forming units-erythroid), which differentiate into late colony-forming units erythroid (CFU-E) and proerythroblasts. BFU-E represent the earliest progenitors committed exclusively to erythroid maturation and a quiescent reserve because only 10% to 20% are in cycle at any given time. CFU-E is more differentiated than BFU-E and most of these progenitors (60–80%) are already in cycle. The earliest recognizable erythroid cells are the proerythroblasts, which differentiate in basophilic erythroblasts, followed by polychromatophilic and orthochromatic erythroblasts. After the last mitotic division, the inactive dense nucleus of the orthochromatic erythroblast is extruded and the resulting mature enucleated cell is a reticulocyte. Mature red blood cells are biconcave disks without mithocondria and other organelles, but with a very high concentration of hemoglobin able to bind and deliver O2 [29, for an exhaustive review see 31–37]. Fig. 3 schematically represents the pathway of erythropoiesis from progenitors to mature cells. The blood has a very important role in the functions of the organism from the earliest moments of its development, so that during embryonic life the various stages of the hematopoietic process alternate at different sites according to the different stages of development [38–39]. The embryonic → fetal hematopoiesis is characterized by three fundamental periods of activity progressively involving the yolk sac, liver and bone marrow. The first period, during which hematopoiesis is localized at the yolk sac, begins between the 14th and 19th days of embryonic life and continues until the completion of the 3rd month [38–39]. Starting from the third month, the second phase of hematopoiesis takes place in the liver where it reaches its maximum during the 3rd–4th month and remains active until a few weeks before birth, when the definitive

hematopoiesis (third phase) is concentrated only in the bone marrow and it will continue throughout adult life [38]. In this system of hematopoietic differentiation four compartments may be identified: stem cells, the progenitors (cellular compartments), precursors, and mature elements of circulating blood (maturation compartments) [39]. Hematopoietic stem cells are characterized by the ability to self-renew (i.e., to generate other totipotent stem cells) and differentiate into hematopoietic progenitor cells. Stem cells also show the important property to remain for a long time in a state of quiescence during adult life [36–37,39–40]. Primitive progenitors are able to generate blast colonies (CFU-B), the progenitors of high proliferative potential (HPP-CFC, colony-forming cells that power high-proliferative), and finally the multipotent progenitors that are still capable of generating mixed colonies, belonging to the different types of hematopoietic differentiation: erythroid, granulocyte, monocyte, and megakaryocytic (the CFU-GEMM) [37,41–42]. Mature progenitors are committed to the differentiation towards a singular hematopoietic lineage and are functionally defined as early burst forming units (BFUs) or more differentiated colony forming units (CFUs): erythroid progenitors are BFU-E and CFU-E; granulocytic-macrophagic progenitors are CFU-GM, CFU-G and CFU-M; finally megakaryocitc progenitors are BFU-Mk and CFU-Mk [37,41–42]. The proliferation, maturation and differentiation of hematopoietic stem cells and progenitors are regulated by the interaction of several hematopoietic growth factors with specific membrane receptors and the consequent activation of the appropriate signal transduction pathways. These factors are also known as colony stimulating factors (CSFs), interleukins (ILs), or hemopoietins and are produced from accessory cells such as macrophages, lymphocytes, fibroblasts, and endothelial cells. They can be classified into three categories, depending on their mechanism of action during hemopoietic differentiation (Fig.3) [34,39]. In the first category are growth factors acting at the earliest stages of hematopoiesis, i.e. the stem cell factor (SCF) [43], FLT-3 ligand (FL) [44,45], the basic fibroblast growth factor (bFGF) [46,47], and interleukin-6 (IL-6) [48]. IL-3 and GM-CSF, growth factors acting as multilineage, belong to the second category and are able to stimulate primitive progenitors to proliferate and differentiate into all hematopoietic lineage [49]. The third category includes the unilineage growth factors acting on progenitors already committed and promoting the production of mature cells in the circulating blood, i.e. erythropoietin (EPO) [50–51], the granulocytic growth factor (G-CSF) [52], monocytic growth factor (M-CSF) [53], and thrombopoietin (TPO) [54]. During hematopoietic differentiation, the maintenance of iron homeostasis is essential for erythrocytes and macrophages. Erythroid cells need to incorporate very high amounts of iron to support the continued synthesis of heme and hemoglobin, while the macrophage cells play a key role in the storage and recycling of iron [29,39,55–56]. During the differentiation of erythroid progenitors towards mature red cells the following morphologically recognizable stages can be distinguished: 1) the earlier stage of proerythroblast, that presents a nucleus relatively large in respect to the cytoplasm, and one or two nucleoli; 2) the more advanced basophilic erythroblast, characterized by a reduced cellular diameter, a nuclear volume reduced more rapidly than the cytoplasm, and a cytoplasm uniformly basophilic; 3) the polychromatophilic erythroblast, that shows the initial condensation of the nucleus, nucleoli no longer visible and the cytoplasm with acidophilic areas; 4) the orthochromatic erythroblast, with a nucleus:cytoplasm ratio of approximately 1:4, nucleus darker and subject to pyknotic degeneration, and cytoplasm slightly pink as a consequence of the progressive increase in hemoglobin concentration; and finally 5) the reticulocyte that has lost its nucleus and, through the complete

degradation of ribosomes and mitochondria, proceeds to the transformation in mature erythrocyte [34,37,39,42,57–58]. In adult mammalian bone marrow erythroblasts are always associated with the erythroblastic islets that represent the drive amplification stage anatomy of erythropoiesis and consists of 1 or 2 histiocytic crown cells surrounded by erythroblasts at all stages of maturation. The histiocytes have thin cytoplasmic extensions that insert between erythroblasts suggesting that factors of nutrition can be provided by the histiocytic cell, centrally located, to the peripheral maturing erythroblasts [37,39,42]. The most important factor involved in the control of erythropoiesis is erythropoietin, but other substances, particularly hormones, contribute to the regulation of this process [59]. Transferrin comes out from the bone marrow sinusoids using ample fenestrature exits, and binds to surface receptors carried by erythroblasts. The iron transferred from transferrin and transported to the mitochondria is reduced from Fe^{3+} to Fe^{2+} and then inserted into protoporphyrin IX by tetrapyrroles heme synthetase (Heme Synthetase HS) for the synthesis of heme [39,55–56,59]. The reticuloendothelial system is a functional unit that includes cells having heterogeneous histologically different identities and a widespread distribution throughout the body, which share the common property of phagocytic activity, e.g. endothelial cells of blood capillaries of liver, spleen, bone marrow and lymph-nodes, tissue and circulating macrophages [59–60]. The reticuloendothelial system is the most important source of iron that enters the blood compartment. The flow of iron from the reticuloendothelial plasma is unidirectional, as the reticuloendothelial cells are not able to pick up the metal from transferrin, but receive only hemoglobin or ferritin iron [59–60]. Senescent erythrocytes at the end of their life (approximately 120–days) are phagocytized by endothelial cells and represent the largest source of iron entering the reticuloendothelial system. About 85% of the iron that enters the reticuloendothelial cells is promptly transferred to plasma transferrin and the remaining 15% is stored as intracellular ferritin, and transferred to plasma much more slowly [39,42,59–60]. The production of red blood cells is regulated by a complex network of transcription factors, among which GATA-1 is considered the master gene of erythropoiesis. GATA-1 positively regulates specific erythroid genes such as erythropoietin receptor (EpoR), glycophorin (GpA), and globin chains and, together with the transcription factor STAT5, induces the expression of the antiapoptotic protein Bcl-xL (Fig.3 and Table 2) [61–63]. The program of erythroid proliferation and differentiation must be positively and negatively regulated to ensure a continuous but tightly controlled production of red blood cells. Erythropoiesis is positively controlled by the combined effect of two major cytokinesis, SCF and Epo. SCF is produced by stromal cells and exerts its effects on erythroid cells mainly during the early and late stages of differentiation of erythroid progenitors, and may act also on immature erythroid precursors. Epo is responsible for the finely tuned homeostatic control of erythrocyte numbers by tissue oxygenation. Epo exerts its effect by stimulating Epo-R. The binding of Epo with the EpoR induces a conformational change that activates the pre-bound, cytoplasmic tyrosine kinase JAK2. The activation of JAK2 induces multiple signaling pathways involving P13 kinase, Akt and STAT5, which prevent apoptosis, supporting erythroid progenitors proliferation and differentiation (Fig.3) [63–66]. However, a negative control of erythropoiesis is clearly required at several levels to avoid overproduction of erythroid cells and polycythemia, which may lead to hyperviscosity and ultimately to thrombosis. The negative regulation is mainly due to apoptosis, a fundamental cellular mechanism allowing clearance of unneeded or potentially dangerous cells. Caspases appear to play a critical role in erythroid apoptotic programs. Caspases belong to a

family of cysteine-dependent and aspartate-specific proteases and, in particular, two classes are described: initiators (caspase-8 and –9) and effectors (caspase-3 and –7). Caspase-8 is activated by the death receptor pathway and caspase-9 by events causing intracellular damages and alterations in mitochondrial membrane potential. Activated caspase –8 and caspase –9 then activate effectors such as caspase –3 that cleaves GATA-1, Tal-1, and proteins involved in cytoplasm, nucleus, and DNA integrity, which allow the cell death program to occur. Death receptors of the TNF receptor (TNF-R) superfamilies (Fas-L, TNF-α, TRAIL) activate the extrinsic apoptotic pathway. Some studies suggest the existence of a negative regulatory feedback operating at low Epo level in a paracrine pathway. Briefly the control of mature red blood cell production may be summarized as follow: at low doses of Epo, cells die by apoptosis, at intermediate doses, cells are arrested in their maturation or enter a program of apoptosis, depending on the number of mature erythroblasts in the bone marrow, and at high doses of Epo, erythroid progenitors and precursors pursue their maturation independently of the number of mature erythroid precursors [63,67–68]. In summary, the emerging picture is that certain genes, such as SCL, are absolutely required for hematopoietic development, whereas others, such as GATA- 2, c-Myb, CBF and some downstream signal transducing molecules, such as Jack 2 and STAT5, are responsible for expansion and maintenance of a normal pool of fetal liver and adult hematopoietic progenitors. The participation of many of these molecules in multicomponent molecular complexes with protein/protein and protein/DNA interactions (e.g., LMO2/Lmbd1/SCL/GATA), during the early, proliferative stages of hematopoiesis may underlie their role in the proliferation and maintenance of immature progenitor/precursor pools in erythropoiesis [69]. Other genes such as GATA1, its partner FOG1, and EKLF are necessary to direct high levels of function of erythroid-specific genes in cells already committed to terminal differentiation. Thus, a hierarchical requirement in the expression of specific regulators during early versus late erythroid differentiation or during embryonic versus fetal liver/adult erythropoiesis is established.

Figure 3. A) Pathway of the erythropoiesis from progenitors to mature cells. Different stages are indicated: hematopoietic stem cell (HSC), burst-forming unit erythroid (BFU-E), colony-forming unit erythroid (CFU-E), proerythroblast (ProE), basophylic (BasoE), polychromatic (PolyE), and orthochromatic erythroblast (OrthoE). **B)** Erythroid transcrip-

tion factors: basic helix-loop-helix factor (TAL1); Lim-domain partner of TAL1 (LMO2); zinc finger factors that bind GATA sequences (GATA-1, GATA-2); GATA-1 partner, friend of GATA (FOG); erythroid Kruppel-like factor (EKLF) and p45NF-E2 (NF-E2). **C)** Receptors for hematopoietic growth factors: stem cell factor-receptor/c-kit; erythropoietin receptor (EPO-R) and insulin-like growth factor-1 receptor (IGF-1-R). **D)** Proteins related to erythrocyte structure and function. Modified by [39] and [32].

Trans-acting factor	Binding motif	Role in hematopoiesis	Target genes	Phenotype of gene inactivation	Human pathology
GATA-1	(A/T) GATA (A/G)	↑ Erythroid differentiation	Globin, erithroid, specific membrane proteins, GATA-1, GATA-2	Anemia and trombocytopenia	X-linked thalassemia/ trombocytopenia
GATA-2	(A/T) GATA (A/G)	↑ Proliferation ↓ Differentiation	GATA-1, GATA-2	No proliferation of immature progenitors	
FOG-1	None	GATA-1-cofactor		No erythroid maturation	
EKLF	CACC	Promotes terminal erythroid differentiation	Globin	Anaemia	β-thalassemia
SCL	CANNTG (E box)	Specification of hematopoiesis		Absence of prenatal hematopoiesis	Translocation in T-ALL
LM02	Lim domain			Absence of hematopoiesis	T-CELL acute lymphocytic leukemia
Myb	(T/C) AAC (G/T) G	↓ Definitive erythropoiesis		Block in definitive erythropoiesis	
STAT 5	GAS	Antiapoptotic effect at level of erythroid precursors	BCL-XL	Anemia due to apoptosis of erythroid progenitors	
NFE 2	TGAGTCA	Promotes terminal erythroid differentiation in vitro	Enzyme of the haem biosynthetic pathway,globin	trombocytopenia	

Table 2. Major transcription factors/signaling molecules involved in the control of erythropoiesis. DNA-binding sites and known target genes of the indicated transcription factors together with the phenotype of their gene inactivation in mice and the human pathologies associated with gene mutations are shown.

4. Iron metabolism and erythropoiesis

Iron plays a pivotal role in cell survival and proliferation by regulating enzymatic activity and oxidation-reduction reactions. It is essential primarily for ensuring the transport of oxygen and

for the catalysis of reactions involved in electron transfer, nitrogen fixation and DNA synthe-sis, but it is also toxic due to its capacity to react with oxygen and catalyze the production of reactive oxygen species. In solution, iron can exist in two states of oxidation, Fe (II) and Fe (III), and is very poorly soluble at physiological pH, especially when it is in the oxidized form Fe (III). Living organisms have thus developed many proteins to carry iron in biological fluids and transport it through cellular membranes, and to store it in a non-toxic and easily mobilizable form [70–72]. Erythropoiesis and iron metabolism are processes closely linked to each other. The large majority of iron in our body is utilized by the erythropoietic system to generate functionally active hemoglobin molecules, which are harbored in the red blood cells. It is estimated that 1800 mg of iron in our body is present in red blood cells, 300 mg in the bone marrow and 600 mg in the reticuloendothelial macrophages of the spleen [71], accounting for more than 60% of total body iron. Approximately 10% is present in muscle fibers (in myoglo-bin) and other tissues (in enzymes and cytochromes) and the remaining body iron is stored in the liver. The normal diet contains 15–20 mg of iron, and the body absorbs 1–2 mg/d of dietary iron. This is balanced with losses via sloughed intestinal mucosal cells, menstruation and other blood losses. Therefore, internal turnover of iron is essential to meet the bone marrow require-ments for erythropoiesis (20–30 mg/d) (Fig. 4) [73–75]. This massive utilization of iron by the erythropoietic system requires the presence of finely tuned regulatory systems that allow storage, mobilization and traffic of iron and at the same time prevent toxicity due to highly reactive iron ions. Because there are no physiologically regulated means of iron excretion, dietary iron absorption is highly regulated primarily at the level of duodenal enterocytes. Other important regulatory sites are the liver and the spleen. Hepatocytes and Kuppfer cells can store large quantities of iron, while iron from senescent red blood cells is recycled from macrophag-es in the spleen. All three compartments are of pivotal importance for erythropoiesis since they control the bioavailability of iron to erythroid progenitors, and all of them respond to hepci-din, the master regulator of iron metabolism [76]. A summary of proteins involved in iron homeostasis, as well as their most frequently used acronyms, is given in Table 3 and Table 4. Transferrin is the main plasma iron transporter that binds two molecules of ferric iron (Fe3+). At the systemic level, transferrin satuaration is the main iron sensor and plays a role in controlling the levels of the iron-regulatory peptide hepcidin [77]. Transferrin is usually between 20 and 30% satured with iron. At the cellular level we known two common mechanisms that can be applied to most of the proteins involved in iron metabolism regulation. First, iron- regulatory proteins 1 (IRP1) and 2 (IRP2) bind to iron-response elements (IREs) in the untranslated regions (UTRs) of mRNA encoding protein involved in cellular iron uptake, storage, and export. IRP1 and IRP2 bind to IREs under conditions of low iron, and they dissociate from IREs in high-iron states [77–78]. If the IRE is in 3'UTR, IRP binding stabilizes the mRNA, prevents degrada-tion, and increases protein production. If the IRE is in the 5'UTR, mRNA translation is inihibited. There are over 35 mRNAs, including hypoxia-inducible factor 2α, that have an IRE and are responsive to iron. The second general mechanism imparts tissue-specific sensitivity to iron balance by modulation of the proportion of iron-sensitive and iron-insensitive mRNAs. This means that one variant responds to iron levels and one does not. The ratio of IRE to non-IRE differs in different tissues, resulting in differences in responsiveness to iron and differences in loading [77]. In specialized cell types, alternatively spliced non-IRE-containing isoforms of ferroportin [34] and DMT1 [79] mRNAs bypass post-transcriptional regulation by IRPs. Under normal circumstances, dietary ferric iron is reduced by cytochrome B to ferrous iron (Fe 2+) at

the apical brush border of duodenal enterocytes and transported into the cell by DMT1. DMT1 expression is highest at the duodenum and decreases towards the colon. Dietary heme iron is absorbed into the enterocyte via the heme carrier protein-1 Inside the enterocyte, heme is degraded by heme oxygenase and iron is released into the cytosol. The free iron is stored in the cells by ferritin or exported to the plasma by FPN1 [77,80–81]. Exported iron is loaded onto transferrin. Before the loading of transferrin, ferrous iron is oxidized to Fe 3+ by hephaestin. Cells can then take up transferrin-bound iron via transferrin receptor 1 (Tfr1, aka CD71). Erythroblasts, the major iron consuming cells in the organism, mainly take up transferrin-bound iron via transferrin receptor 1 (TfR1). Iron release takes place in vesicles of low pH. Ferric iron is reduced to ferrous iron by Steap3 and subsequently exported into the cytosol via DMT1, while transferrin and TfR1 recycle to the surface. The bulk of intracellular iron in erythroblasts is used for hemoglobin synthesis, where mitochondria are indispensable for heme production. Excess heme is either exported via FLVCR or catabolized via the HO-1 pathway [39,82]. As the intake of nutritional iron is not sufficient to cover the daily iron necessity of erythropoiesis, iron recycling is necessary. Macrophages exert a crucial role in iron recycling, phagocytosing senescent erythrocytes, and releasing accumulated iron back into the circulation in a regulated manner, thus enabling iron recycling [82]. Phagocytosed erythrocytes are broken up in lysosomes, and heme-bound iron is released via HO-1. When body iron levels are low, storage iron re-enters the circulation. Ferroportin again functions as the only known iron exporter, and another plasma copper-containing ferroxidase coeruloplasmina converts ferrous into ferric iron before its loading onto transferrin [82]. Similar to reticuloendothelial cells, hepatocytes are an important site of iron storage in the form of ferritin. Most important, hepatocytes serve a central role in iron homeostasis as the site of regulated production of the hormone hepcidin. Hepcidin functions as the "hypoferremia hormone" by down-regulating the ferroportin-mediated release of iron into the circulation [83]. The consequent iron retention in duodenal enterocytes decreases dietary iron absorption and the iron retention in reticuloendothelial macrophages decreases iron turnover. Hepatocellular hepcidin production is regulated by signals reflecting inflammation, iron status, erythropoietic activity, and oxygen tension [83]. Major pathways of iron traffic between cells and tissues are indicated in Fig. 4.

Figure 4. Major pathways of iron traffic between cells and tissues.

Protein name	Acronyms	Funcion in iron metabolism	Localization
Iron aquisition			
Transferrin	Tf	Plasma iron transfer	Plasma
Transferrin receptor 1	TfR1	Internalization of holo-Tf	Ubiquitously expressed
Six transmembrane epithelial antigen of the prostate 3	STEAP3	Ferric reductase in the endosomes of erythroid cells	erythroblast
Divalent metal transporter 1	DMT1	Epithelial/endosomal transport of ferrous iron	Enterocyte (apical membrane)
Duodenal cytochrome b	Dcytb	Apical membrane ferric reductase of enterocytes	Enterocyte (apical membrane)
Heme oxygenase 1	HO-1	Degradation of hemoglobin for Fe^{2+} release	Enterocyte
Ferritin	Ft	Cellular iron storage and uptake	Enterocyte, erythroblast , macrophage, hepatocyte, myocytes and cardiomyocytes
Intracellular iron transport			
Mitoferrin 1/2	MFRN 1/2	Import of ferrous iron to mitochondria	Erythroblast (mitochondria)
Iron efflux			
Ferroportin	FPN1	Export of ferrous iron	Enterocyte (basolateral membrane) Macrophages, hepatocytes, Erythroid cells
Hephaestin	HEPH	Membrane-bound ferroxidase	Enterocyte (basolateral)
Ceruloplasmin	CP	Plasma ferroxidase	macrophage
Feline leukemia virus, subgroup C, receptor	FLVCR	Heme export	Erythroblast

Table 3. Main proteins involved in iron homeostasis

PROTEIN NAME Systemic iron metabolism	Acronyms	Function	Phenotype due to loss of function
Hepcidin	HEPC	Inhibition of ferroportin mediated efflux	Absent hepcidin expression. Iron overload at the level of liver and pancreas and at a lesser extent of heart (HH type2A)

PROTEIN NAME Systemic iron metabolism	Acronyms	Function	Phenotype due to loss of function
Bone morphogenetic protein 6	BMP6	Regulation of hepcidin expression in response to hepatic iron	Iron overload with decreased levels of hepcidin
Hemojuvelin	HJV	Enhancement of BMP signaling to hepcidin	Early onset severe iron overload with suppressed hepcidin expression (HH type2A)
Transferrin	Tf	Plasma iron transfer	Iron deficiency anemia with tissue iron overload
High Fe protein	HFE	Regulation of hepcidin expression by plasma iron	Iron overload with decreased levels of hepcidin (HH type 1)
Transferrin receptor 2	TfR2	Regulation of hepcidin expression by plasma iron	Iron overload with decreased levels of hepcidin (HH type 3)
SMAD 4	SMAD4	Signaling to hepcidin	Decreased hepcidin levels and iron overload
Matriptase-2	TMPRSS6	Proteolytic cleavage of Hjv	Macrocytic anemia with low iron stores and increased hepcidin
Neogenin	NEO	Regulation of Hjv	Hepatic iron overload
Cellular iron metabolism			
Iron regulatory protein 1 IRP 1		Post-transcriptional regulation of IRE-containing mRNAs	Not known
Iron regulatory protein 2 IRP 2		Post-transcriptional regulation of IRE-containing mRNAs	Misregulation of iron metabolism. Neurodegenerative disease due to iron accumulation in neurons and oligodendrocytes
F-box and leucine-rich repeat protein 5	FBXL 5	Iron-dependent ubiquitination and degradation of IRP 2	Embryonic lethality

Table 4. Main proteins involved in iron homeostasis regulation

5. Hepcidin: The link between erythropoiesis and iron regulation

In recent years, there has been important advancement in our understanding of iron metabolism, mainly as a result of the discovery of hepcidin, a key regulator of whole body iron homeostasis originally identified from urine as an antimicrobial peptide produced in the

hepatocytes [84]. The aim of this chapter is beyond a complete picture of current knowledge on the hepcidin regulation, therefore I will focus only on those aspects that influence erythro-poiesis directly or indirectly. Targeted deletion of the HAMP gene in mice or mutations in the human HAMP gene result in massive iron overload [85]. Conversely, high levels of hepcidin lead to decreased iron absorption and iron-restricted anemias. Therefore, hepcidin is a negative regulator of iron transport into plasma. Experimental data suggested that the hepcidin could be the regulator of iron absorption and recycling acting principally or solely by binding to ferroportin, the only known cellular iron exporter. The hepcidin-ferroportin interaction controls systemic iron homeostasis: hepcidin binds to ferroportin and induces its internaliza-tion and degradation. This mechanism regulates the distribution of iron in the body. When hepcidin levels are low, iron-exporting cells, including duodenal enterocytes, macrophages, and hepatocytes display abundant ferroportin and release iron into plasma. When hepcidin concentration increase, hepcidin binds to ferroportin, causing its phosphorylation, internali-zation, ubiquitylation, sorting through the multivesicular body pathway, and degradation in lysosomes, and iron is retained within cells in cytoplasmic ferritin [34,82,86–89]. Hepcidin is regulated at transcriptional level by different stimuli that can act as positive or negative regulators. The membrane isoform of hemojuvelin (HJV), transferrin receptor 2 (TfR2), IL-6, iron and the hemochromatosis protein HFE are all positive regulators of hepcidin transcrip-tion. On the contrary, hypoxia, anemia, iron deficiency, and erythroid expansion are all negative regulators of hepcidin expression. We know four major regulatory pathways that act through different signaling pathways to control the transcription of hepcidin, e.g. iron erythroid demand, hypoxia, iron store, and inflammation. Briefly, hepcidin transcription is activated by BMP-6 (Bone morphogenetic protein 6) via the SMAD pathway. Hemojuvelin (HJV) enhances the activity of the BMP receptor (BMP-R), while cleavage of HJV by TMPRSS6 suppresses this activity. Diferric Tf displaces the hemochromatosis protein (HFE) from the high-affinity transferrin receptor (TfR1) that associates with TfR2 enhancing signaling via BMP-R. Inflammatory cytokine IL-6 acts through its receptor (IL6-R) and the JAK2/STAT3 pathway to turn on hepcidin production. Growth differentiation factor 15 (GDF15), twisted gastrulation-1, erythroferrone (ERFE), hypoxia, and erythropoietin (Epo) reduce hepcidin transcription [89–93]. GDF15 is released by erythroid precursors and increased in hemoglobi-nopathies, e.g. thalassemia, congenital dyserythropoietic anemia type 1, and refractory anemia with ring sideroblasts. GDF15 is decreased post transfusion, in parallel with EPO and de-creased marrow activity, resulting in increase in hepcidin. Twisted gastrulation (TWSG1), soluble HJV, and erythroferrone (ERFE) are other factors that are rapidly produced with increased erythroid activity and result in reduced hepcidin production. ERFE belongs to the C1q-tumor necrosis factor-related family of proteins. In response to EPO, ERFE is rapidly produced by erythroid precursors in the bone marrow and the spleen via signal transducer and activator of transcription 5 (STAT5). The canonical Janus kinase 2 (Jak2)/Stat5 signaling pathway is a known mediator of EPO response and stress erythropoiesis. Further work is necessary to confirm whether ERFE is the long-sought erythroid regulator responsible for hepcidin suppression and iron overload in patients with hereditary iron- loading anemia [92, 94–97]. Regulation of hepcidin production is shown in Fig.5
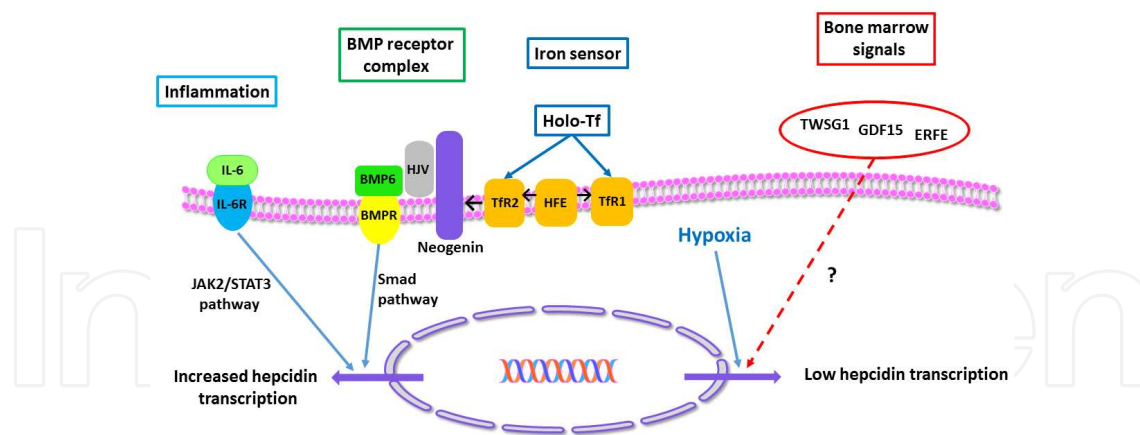

Figure 5. Iron-mediated regulation of hepcidin levels on hepatocytes.

6. Ineffective erythropoiesis and iron overload in β-thalassemia

In β-thalassemia the erythropoietic process is markedly altered and is referred to as ineffective erythropoiesis (IE). The lack or reduced synthesis of β-globin chains induces an excess of free α-globin chains within erythroid cells. Aggregation, denaturation, and degradation of these chains leads to the formation of insoluble precipitates that cause oxidative membrane damage within the red blood cell and developing erythroblasts [98]. In β-thalassemia the process of IE is accompanied by a massive iron overload, due to an increased rate of iron absorption by the gastrointestinal (GI) tract and to frequent blood transfusions. Nevertheless, iron overload occurs also in patients who have not received transfusions such as patients suffering from thalassemia intermedia [63,99]. In patients who are iron- overloaded, the capacity of serum transferrin to bind iron may be exceeded, which means that a non-transferrin-bound fraction of iron may circulate in the plasma. This unbound iron, which is carried in the iron storage protein ferritin, can promote the generation of free hydroxyl radicals, which propagate oxygen-related tissue damage. Additionally, insoluble iron complexes called hemosiderins may become deposited in body tissues causing toxicity and death. Cardiac failure is a major complication of iron overload. Iron deposition can cause myocarditis and cardiac fibrosis. There are a number of other possible complications of iron overload: excess iron deposition in the liver can lead to fibrosis/cirrhosis or cancer, and diabetes mellitus may occur as a result of beta-cell destruction secondary to iron overload in the pancreas. Excess iron overload in the pituitary may cause growth failure due to hypogonadism and infertility due to reduced gonadotropin levels [86,100–101]. If iron were a dominant regulator, patients with β-thalassemia should express very high levels of hepcidin in serum in order to decrease intestinal iron absorption. In contrast, the levels of hepcidin are very low in these patients, suggesting that the ineffective erythropoiesis alone is able to suppress the synthesis of hepcidin in spite of the presence of a severe iron overload [89,102–104]. Hepcidin deficiency develops as a result of a suppressive signal generated by the greatly expanded erythroid precursor population. This also leads to excessive iron absorption and the development of iron overload even in patients who are not transfused. Although the hepcidin suppression is partially relieved by erythrocyte

transfusions, the transfusions themselves add large amounts of exogenous iron again leading to iron overload. The observation that serum from β-thalassemic patients inhibited hepcidin mRNA expression in the HepG2 cell line suggested the existence of a negative erythropoietic regulator of hepcidin expression [105]. The nature of this humoral factor is still uncharacterized, but may include one or more proteins during active erythropoiesis. One of this regulators could be the cytokine growth differentiation factor-15 (GDF15) because it was observed that serum from thalassemia patients suppressed hepcidin mRNA expression in primary human hepatocytes and depletion of GDF15 reversed the hepcidin expression. GDF15 is a divergent member of the transforming growth factor-beta superfamily that is secreted by erythroid precursors and other tissues. It has been identified as an oxygen-regulated transcript responding to hypoxia and as a molecule involved in hepcidin regulation. It was suggested that GDF15 overexpression arising from an expanded erythroid compartment contributed to iron overload in thalassemia syndromes by inhibiting hepcidin expression, possibly by antagonizing the BMP pathway [89,93]. GDF15 mRNA levels and secreted protein were up-regulated in response to iron depletion in a range of human cell lines and "in vivo" in humans and this up-regulation was independent of HIF suggesting the existence of a novel iron and oxygen-sensing pathway [106]. Finally, the observation that GDF15 was induced by over-expression of wild type ferroportin connects the iron-mediated regulation of GDF15 concentration to patho-physiological levels of iron. Despite systemic iron overload, ineffective erythropoiesis and associated iron-fluxes in beta-thalassemia might generate an iron deficiency signal in a relevant molecular or cellular context and consequent stimulation of GDF15 expression in a particular erythroid compartment [106]. Experimental data provided the evidence that TWSG1 could be potentially involved in the regulation of hepcidin by erythropoiesis. In contrast to GDF15, the expression of human twisted gastrulation factor (TWSG1) occurs early during erythroblast maturation before hemoglobinization of the cells. TWSG1 is another highly expressed serum protein in thalassemia suppressing hepcidin transcription by interfering with BMP signaling either directly, by acting on BMP receptors, or indirectly by influencing circulating BMP2 and BMP4 levels. So it was proposed that TWSG1 might act with GDF15 to dysregulate iron homeostasis in β-thalassemia [107]. Results obtained by HuH7 hepatoma cells cocultered with primary human erythroblasts or erythroleukemic UT7 cells presented a 20- to 35-fold increase of hepcidin expression and identified OsM responsible for this increase of hepcidin levels. In contrast to GDF15 and TWSG1, it was showed that OsM could induce hepcidin transcription in human hepatoma cell lines mainly through the JAK/STAT pathways [108–109].

7. New therapeutic approaches to limit iron absorption in β-thalassemia

For its frequency and severity β-thalassemia represents a significant health problem in various areas of the world. Conventional treatment of thalassemia includes transfusion therapy, iron chelation therapy and, in rare cases, splenectomy. Regular blood transfusions in combination with aggressive iron chelation have been remarkably effective in delaying the onset of iron-related organ failure and improving mortality but, in spite of this, many patients continue to be affected by cardiac disease and other clinical complications, e.g. develop endocrine failure and delayed pubertal maturation. To add that this rigorous life-long treatment regime is

onerous and represents an enormous imposition on quality of life. Allogeneic hemopoietic stem cell transplantation is the only approach that may lead to a definitive cure but it is not available to most patients. The understanding of β-thalassemia pathophysiology has involved more than 50 years of biochemical and biological studies leading to the development of alternative therapies to cure or ameliorate the disease. New potential molecular targets for β-thalassemic therapy can be divided into three categories. To the first category belong the primary targets that include all of the molecular defects that lead to a decrease in β-globin synthesis. Hemopoietic stem cell transplantation (HSCT), gene therapy using viral vectors and antisense mRNA are an example of strategies targeting the primary causes of reduced β-globin expression. To the second category belong the secondary targets including modifiers of chain imbalance in β-thalassemia by increasing of γ-globin synthesis. Gene therapy approaches for the induction of HbF synthesis include transduction of lentiviral vectors incorporating γ-globin/β-LCR, or attemps to promote endogenous gamma-globin expression using artificial transcription factors. Pharmacological approaches for the induction of gamma-synthesis include the treatment with erythropoietin (EPO) preparations, or short chain fatty acid derivatives (SCFADs) or chemotherapeutic agents as hydroxycarbamide (HU) and 5-azacytidine. To the third category belong the tertiary targets that are those directed at treating the complications of β-thalassemia such as iron overloading and oxidative cellular damage [23–25,89]. In recent years increasing experimental evidences indicated that there was a potential for therapeutic intervention in β-thalassemia by means of manipulating iron metabolism [110–113]. In mice that completely lack Stat5 activity, it was observed that cell surface levels of TfR1 on erythroid cells were decreased more than 2-fold suggesting a link between EpoR/Jak/Stat signaling and iron metabolism [114]. Another study suggested a direct involvement of Epo in hepcidin regulation through the transcriptional factor C/EBP alpha [115]. It was also observed a link between Jak2 and FPN1: Jak2 phosphorylates FPN1 following its binding to hepcidin triggering its internalization and degradation [116]. Therefore, Jack2 might represent one of the major links at the interface between erythropoiesis and iron metabolism suggesting that use of Jak2 inhibitors, antioxidant, and analog of the hepcidin might reduce ineffective erythropoiesis and abnormal iron absorption. Several JAK2 inhibitors have already been developed, showing significant and beneficial results in myelofibrosis and JAK2-related polycythemia vera [117]. However, trials with JAK2 inhibitors in myeloproliferative disorders have also shown several side effects, among them thrombocytopenia and anemia. On the contrary, in preclinical thalassemic models, splenomegaly was reversed in less than two weeks and no side effects were observed [117]. Administration of synthetic hepcidin or of agents that increase its expression, may be beneficial in controlling absorption of this metal. Hepcidin agonists or stimulators of hepcidin production are being developed for the treatment or prevention of iron overload in hepcidin deficiency states, including hereditary hemochromatosis and β-thalassemia. It was observed that transgenic hepcidin therapy improved iron overload as well as erythropoiesis in the mouse model of β-thalassemia [118]. The rationale for the use of hepcidin agonists is justified by two principal observations: first, the phlebotomy is an inexpensive and effective treatment for iron overload that is acceptable to must but not all patients affected by hereditary hemochromatosis; second, the iron-loading anemias cannot be treated in this manner and require iron chelation therapy, which is not well tolerated by many patients. Hepcidin agonists are agents that replace hepcidin activity or stimulate its

endogenous production and, in both of hereditary hemochromatosis and iron-loading anemias, could prevent iron accumulation by redistributing iron from parenchymal tissues to macrophages where iron is less toxic. Results obtained treating a mouse model of β-thalassemia with hepcidin agonists suggested that the use of these agents could not only prevent iron overload but could also improve erythropoiesis, perhaps by decreasing excessive alpha-globin synthesis or diminishing oxidative stress in erythropoietic precursors [119–120]. Minihepcidins are short peptide mimetics (9AA long) that are sufficient to induce FPN1 degradation in reporter cells. The extracellular loop of ferroportin surrounding the thiol cysteine C326 appears to be essential for hepcidin binding, as indicated by the lack of hepcidin binding to otherwise fully functional ferroportin containing the isosteric mutation C326S [119]. Analysis of the interface between hepcidin and ferroportin showed that the segment composed of a 9 N-terminal amino acid segment of hepcidin is sufficient for binding and internalization of ferroportin [121]. These small modified mini-hepcidin peptides show bioactivity in vivo, as determined by their ability to induce hypoferremia in mice and to prevent iron accumulation in hepcidin-deficient mice [119]. Potential drug target also is the transmembrane protease serine 6 (TMPRSS6) or Matriptase-2, a transmembrane serine protease that attenuates hepcidin expression. The fundamental role of TMPRSS6 on hepcidin expression is underscored by the observation that patients and mice with mutations in this gene are affected by iron-refractory iron deficiency anemia (IRIDA) [117]. In Hbbth3/+ mice, use of both antisens oligonucleotide (Tmprss6-ASO9) and RNA interference (Tmprss6-siRNA) can reduce the synthesis of transmembrane serine protease TMPRSS6 by degrading the corresponding mRNA. This led to increased hepcidin expression, decreased Tf-sat, and reduction of hemichrome formation and apoptosis in erythroid cells suggesting that these Tmprss6 inhibitors could be beneficial in individuals with β-thalassemia [117]. Hepcidin levels can be also altered by targeting a bone morphogenetic protein-dependent (BMP-dependent) pathway known to be central to the regulation of hepcidin expression. This pathway involves a multitude of extracellular factors such as GDF15 and TWSG1. These factors are both BMP antagonists produced by erythroblasts that inhibit hepcidin expression in vitro, suggesting their role as putative components of the erythroid regulator [122]. A major goal of hemoglobinopathy research is to develop treatments that correct the underlying molecular defects responsible for β-thalassemia. One approach to achieving this goal is the reactivation of γ-globin synthesis by farmacologic induction. Many of the events controlling the activity of the β-globin locus are known, but the details of those regulating normal human hemoglobin switching and reactivation of HbF in adult hematopoietic cells remain to be elucidated. Agents that increase human HbF in patients may work at one or more levels: for example, hydroxyurea and 5-azacytidine kill dividing cells preferentially and may increase γ-globin expression indirectly through this effect; butyrate may work both by increasing γ-globin translation on ribosomes and by inhibition of histone deacetylase (HDAC) [39, 112,123]. It was showed that Stem Cell Factor (SCF) induced an "in vitro" expansion of effective erythropoiesis and a reactivation of γ-globin synthesis up to fetal levels, paving the way to its potential use in the therapeutic treatment of this disease [124]. Recently it was reported the ability of thalidomide to increase γ-globin gene expression and the proportion of HbF-containing cells in a human "in vitro" erythroid differentiation system. This study has also showed that thalidomide induced production of ROS causing p38 MAPF phosphorylation and globally increased histone H4 acetylation [125]. However, the mecha-

nisms of action of these agents are not yet defined and their role in β-thalassemia therapy is still being explored in light of its acceptable toxicity profiles adding to their promise as therapeutic agents. Key genes controlling fetal/adult globin switching have been identified (e.g. BCL11 and cMYB) and may ultimately serve as direct targets for small molecules that would increase HbF levels in β-thalassemic patients [126–127]. Finally, the fact that most HbF-inducing agents are cytotoxic and many activate the p38MAPK cell stress signaling pathway suggested the importance of what has been termed the "integrated stress response" pathway in erythroid cells to understanding HbF induction. A variety of stress stimuli activate this pathway in erythroid cells: viral infection, ROS, heat shock, NO, ultraviolet irradiation, endoplasmic reticulum stress, inadequate nutrients, proteasome inhibition and limiting amounts of heme [112].

8. Conclusion

The discovery of hepcidin and its role in iron homeostasis has revolutionized our understanding of the pathogenesis of iron overload and iron-restricted anemias and has stimulated the development of new diagnostic and therapeutic methods for these disorders. Several physiological stimuli regulate the production of the iron-regulatory hormone hepcidin: iron loading, inflammation, and erythropoiesis. These stimuli modulate iron availability for erythropoiesis and other physiological processes and regulate the level of body iron stores by altering hepcidin levels. However, important scientific questions still remain to be answered. Further work is required to understand the mechanisms of hepcidin regulation by iron and erythroid activity; to elucidate the structure, the transport function and the complex regulation of the hepcidin receptor ferroportin; to define the hepcidin role in iron homeostasis. In the coming years, these efforts are likely to yield new therapeutical approaches for the treatment of anemia and iron overload disorders.
